We explore the effects of frequent, impulsive quantum nondemolition measurements of the energy of two-level systems (TLS), alias qubits, in contact with a thermal bath. The resulting entropy and temperature of both the system and the bath are found to be completely determined by the measurement rate, and unrelated to what is expected by standard thermodynamical rules that hold for Markovian baths. These anomalies allow for *very fast control* of heating, cooling and state-purification (entropy reduction) of qubits, much sooner than their thermal equilibration time.

I. INTRODUCTION

Non-Markovian quantum thermodynamics of two level systems (TLS) in contact with a bath has surprising aspects in store. According to standard Markov thermodynamics, the TLS (alias qubit) thermal equilibration process is expected to progress monotonically, accompanied by increase of the entropy, at least on average [1, 2, 3, 4, 5]. Yet drastic deviations from this trend are revealed when considering impulsive disturbances of thermal equilibrium between TLS and a bath [6, 7]. These effects bear certain similarities to the work described in [8]. We have shown [9] that frequent and brief quantum non demolition (QND) measurements of the TLS energy-states entail unfamiliar anomalies of the entropy and temperature of both system and bath, which become unrelated to what is known from standard, Markovian thermodynamic rules[2, 5]: (i) a transition *from heating to cooling* of the TLS ensemble as we vary the interval between consecutive measurements on the time scale of the inverse energy separation of the qubit levels; and (ii) correspondingly, *oscillations* of the entropy relative to that of the equilibrium state.

Here we present an in-depth study of short-time evolution of quantum systems coupled to a bath, interrupted by frequent measurements. We first discuss in Sec. II the initial equilibrium state relevant to our scenario. Sec. III then describes the measurement-induced disturbance of equilibrium. In Sec. IV we present a master equation analysis of the post-measurement evolution and a discussion of the heating and cooling requirements. Cooling conditions and entropy evolution of the system are discussed in Sec. V and VI, respectively. A discussion of possible experimental realizations is given in Sec. VII.

II. SYSTEM-BATH ENTANGLEMENT AT EQUILIBRIUM

A. Hamiltonian

The following Hamiltonian describes the qubit system that interacts with the bath.

$$H_{tot} = H_S + H_B + H_{SB}. \quad (1)$$

Here H_{tot} pertains to the coupled system and bath and consists of:

$$H_S = \hbar\omega_a|e\rangle\langle e|, \quad (2)$$

$$H_B = \hbar \sum_{\lambda} \omega_{\lambda} a_{\lambda}^{\dagger} a_{\lambda}, \quad (3)$$

$$H_{SB} = \mathcal{S}\mathcal{B}, \mathcal{S} = \sigma_x, \quad \mathcal{B} = \hbar \sum_{\lambda} \left(\kappa_{\lambda} a_{\lambda} + \kappa_{\lambda}^* a_{\lambda}^{\dagger} \right), \quad (4)$$

where $\mathcal{S}$ and $\mathcal{B}$ are the system and bath operators, respectively, in the system-bath interaction H_{SB} , a_{λ} ($a_{\lambda}^{\dagger}$) are the annihilation (creation) operators, and κ_{λ} is the matrix element of the weak coupling to bath mode λ . We stress that in the interaction Hamiltonian (H_{SB}) we *do not* invoke the rotating-wave approximation (RWA)[10], namely, we do not impose energy conservation between the system and the bath, on the time scales considered[11].

B. Qubit state mixedness at equilibrium

At equilibrium, the qubit and the bath are in an entangled state. To find the mean energy mixedness (impurity) of the qubit (TLS) at a given temperature T , one needs the equilibrium density matrix for the total system $\rho_{Eq} = \exp(-\beta H_{tot})/Z$, where Z is the partition function and $1/\beta = k_B T$.

Using Heims perturbation theory [12] one can expand

ρ_{Eq} as

$$\begin{aligned}\rho_{Eq} &= \frac{1}{Z} e^{-\beta(H_0 + H_{SB})} \\ &= \frac{1}{Z} e^{-\beta H_0} [1 + \epsilon S_1 + \epsilon^2 S_2 + O(\epsilon^3) + \dots],\end{aligned}\quad (5)$$

where

$$\epsilon = \max(\eta_k / \hbar \omega_a),$$

is a small dimensionless parameter normalizing the rate η_k of the maximally coupled mode to the TLS natural frequency, and

$$\epsilon S_1 = \beta \int_0^1 dx e^{x\beta H_0} H_{SB} e^{-x\beta H_0}, \quad (6a)$$

$$\begin{aligned}\epsilon^2 S_2 &= \\ \beta^2 \int_0^1 dx \int_0^x dy e^{x\beta H_0} H_{SB} e^{-(x-y)\beta H_0} H_{SB} e^{-y\beta H_0}.\end{aligned}\quad (6b)$$

Noting that $e^{-\beta H_0} = Z_0 \rho_S \otimes \rho_B$, where ρ_S and ρ_B are the equilibrium density matrices for the system and the bath without interaction, the trace over the bath degrees of freedom can be performed. The state of the system is diagonal in the σ_z basis and is given by

$$\rho_S(\epsilon) = \frac{1}{2} (\mathcal{I} + P_{Eq}(\epsilon) \sigma_z).$$

The qubit purity at equilibrium is given by

$$\begin{aligned}P_{Eq}(\epsilon) &= \\ \frac{P_{Eq} + \epsilon^2 \int_{-\infty}^{\infty} d\omega G_T(\omega) [P_{Eq}^+ \mathcal{K}^+(\omega) - P_{Eq}^- \mathcal{K}^-(\omega)]}{1 + \epsilon^2 \int_{-\infty}^{\infty} d\omega G_T(\omega) [P_{Eq}^+ \mathcal{K}^+(\omega) + P_{Eq}^- \mathcal{K}^-(\omega)]}.\end{aligned}\quad (7)$$

Here the temperature-dependent coupling spectrum

$$G_T(\omega) = G_0(\omega)(n_T(\omega) + 1) + G_0(-\omega)n_T(-\omega), \quad (8a)$$

is written in terms of the average occupation number at inverse temperature $\beta = 1/T$,

$$n_T(\omega) = \frac{1}{\exp(\beta \hbar \omega) - 1}, \quad (8b)$$

and the zero-temperature bath-coupling spectrum

$$G_0(\omega) = \epsilon^2 \sum_k \eta_k^2 (\hbar \omega_a)^2 / \eta_{max}^2 \delta(\omega - \omega_k). \quad (8c)$$

The equilibrium value purity of the TLS is

$$P_{Eq} = \tanh(-\beta \hbar \omega_a / 2), \quad (9)$$

with the ground and excited populations respectively given by

$$\rho_{ee} = P_{Eq}^+ = (1 + P_{Eq}) / 2, \quad (10)$$

$$\rho_{gg} = P_{Eq}^- = (1 - P_{Eq}) / 2. \quad (11)$$

The frequency — and temperature — dependent coefficients in (7) are

$$\begin{aligned}\mathcal{K}^\pm(\omega) &= \frac{1}{(1 \mp \frac{\omega}{\omega_a})^2} [(\cosh \beta \hbar(\omega_a \mp \omega) - 1) \\ &\quad \pm (\sinh \beta \hbar(\omega_a \mp \omega) - \beta \hbar(\omega_a \mp \omega))].\end{aligned}\quad (12)$$

From Eq. (7) it can be seen that even at zero temperature purity is incomplete, $P_{Eq}(\epsilon) < 1$, which is due to the system-bath entanglement. The difference between P_{Eq} in (9) and $P_{Eq}(\epsilon)$ in (7) has a non-monotonic dependence on β . This can be seen from Fig. 1 where we have plotted the relative change of TLS purity with inverse temperature. As the purity drop that we wish to correct is non-monotonic with temperature, so will be the resultant purification.

FIG. 1: Excitation of the TLS at thermal equilibrium as a function of the inverse temperature β either with (dashed) and without (solid) considering the effect of the system-bath interaction. Parameters: memory time of the bath $t_c = 2/\omega_a$, peak of the Lorentzian bath spectrum $\omega_0 = 2\omega_a$, maximal coupling strength to the bath $|\eta_{max}|^2 = \omega_a/100$, where $\hbar \omega_a$ is the energy separation of the TLS.

Using a similar analysis, the mean interaction energy to $O(\epsilon^2)$, is given by

$$\begin{aligned}\langle H_{SB}(\epsilon) \rangle_{Eq} &= -\hbar \omega_a \epsilon^2 \\ &\cdot \frac{\int_{-\infty}^{\infty} d\omega G_T(\omega) [P_{eq}^+ \tilde{\mathcal{K}}^+(\omega) - P_{eq}^- \tilde{\mathcal{K}}^-(\omega)]}{1 + \epsilon^2 \int_{-\infty}^{\infty} d\omega G_T(\omega) [P_{eq}^+ \mathcal{K}^+(\omega) + P_{eq}^- \mathcal{K}^-(\omega)]},\end{aligned}\quad (13a)$$

where the quantity in brackets is dimensionless, and

$$\begin{aligned}\tilde{\mathcal{K}}^\pm &= \frac{1}{1 \mp \frac{\omega}{\omega_a}} \\ &\cdot [\cosh \beta \hbar(\omega_a \mp \omega) - 1 \pm \sinh \beta \hbar(\omega_a \mp \omega)].\end{aligned}\quad (13b)$$

For a Lorentzian coupling spectrum,

$$\eta_k = \eta_{max} \sqrt{\frac{\Gamma^2}{\Gamma^2 + (\omega_0 - \omega_k)^2}}, \quad (14a)$$

the mean interaction-energy at $T = 0K$, is simply given by the bath-induced lamb shift [10]

$$\langle H_{SB} \rangle_{Eq} \approx -\hbar\omega_a \int_0^\infty d\omega \frac{\Gamma^2}{\Gamma^2 + (\omega_0 - \omega)^2} \frac{1}{(1 + \omega/\omega_a)}. \quad (14b)$$

This proves the *negativity* of the mean system-bath interaction energy in equilibrium.

III. DISTURBANCE OF EQUILIBRIUM BY IMPULSIVE QND MEASUREMENT

The Hamiltonian is intermittently perturbed by the coupling of the system (qubit) to the detector (measuring apparatus), designed to effect a QND impulsive measurement in the σ_z -basis. Such a measurement projects the qubit onto the $|e\rangle$ or $|g\rangle$ energy states. We stress that the measurement results are *unread*, i.e., the qubit dynamics is changed by *non-selective measurements*.

A. Dynamic description of the measurement

The time-dependent system-detector coupling (to the k th detector) has the form

$$H_{SD}(t) = \frac{\hbar(t)}{2}(1 + \sigma_z)(|0\rangle\langle 0| + |1\rangle\langle 1| - |0\rangle\langle 1| - |1\rangle\langle 0|). \quad (15)$$

where $(1 + \sigma_z) = |e\rangle\langle e|$ ensures QND measurement of the qubit energy, and

$$\hbar(t) = \frac{\pi}{4\tau} \left(\tanh^2 \left(\frac{t - t_0}{\tau} \right) - 1 \right) \quad (16)$$

is a smooth temporal profile of the system coupling to the detector qubits during the measurement that occurs at time t_0 and has a duration of τ .

The detector (ancilla) qubits have energy-degenerate states $|0\rangle, |1\rangle$ so that we may set the detector Hamiltonian to be zero

$$H_D = 0. \quad (17)$$

This form of the single-measurement Hamiltonian H_{SD} was chosen so that the measurement interval is $[0, \tau]$:

$$e^{-i \int_0^\tau dt H_{SD}(t)/\hbar} = U_C. \quad (18)$$

where U_C denotes to the CNOT operation.

In our model (Eqs. (4) - (18))

$$e^{-i \int_0^\tau dt H_{SD}(t)} |0\rangle_D = U_C |0\rangle_D = |1\rangle_D |e\rangle\langle e| + |0\rangle_D |g\rangle\langle g|. \quad (19)$$

The measurement consists in letting the TLS interact with the detector (a degenerate TLS) via H_{SD} . The measurement outcomes are averaged over (for non-selective

measurements), by tracing out the detector degree of freedom. The total effect on the system density-operator is:

$$\rho_S \mapsto Tr_D \{ U_C \rho_S \otimes |0\rangle_{DD} \langle 0| \} = |e\rangle\langle e| \rho_S |e\rangle\langle e| + |g\rangle\langle g| \rho_S |g\rangle\langle g| \quad (20)$$

i.e., the diagonal elements are unchanged, and the off-diagonals are erased. Since the TLS is entangled with the bath, the effect of the measurement in Eq. (18) is:

$$\begin{aligned} \rho_{tot}(0) &= \rho_{Eq} \rightarrow \rho_{tot}^M = Tr_D \{ U_C \rho_{tot} \otimes |0\rangle_{DD} \langle 0| \} \\ &= |e\rangle\langle e| \rho_{tot} |e\rangle\langle e| + |g\rangle\langle g| \rho_{tot} |g\rangle\langle g| \\ &\equiv \rho_{ee}^B |e\rangle\langle e| + \rho_{gg}^B |g\rangle\langle g|. \end{aligned} \quad (21)$$

Since H_{SD} in Eq. (15) commutes with H_S , we may consider the measurement-induced evolution of $\langle H_{SB}(\tau) \rangle$, rather than $\langle H_{tot}(\tau) \rangle$. In the impulsive limit ($\tau \rightarrow 0$), the measurement yields:

$$\begin{aligned} \langle H_{SB} \rangle_{Eq} &\rightarrow \langle H_{SB}(\tau) \rangle^M \\ &= Tr \left\{ \rho_{tot}(0) {}_D\langle 0| U_C^\dagger H_{SB}(0) U_C |0\rangle_D \right\}. \end{aligned} \quad (22)$$

Finally, using the RHS of (19) and (4), we get:

$$\begin{aligned} {}_D\langle 0| U_C^\dagger H_{SB}(0) U_C |0\rangle_D &= 0 \\ &\rightarrow \langle H_{SB}(\tau) \rangle^M = 0. \end{aligned} \quad (23)$$

In fact, this result follows immediately from the nature of the projective measurement:

$$\begin{aligned} \langle H_{SB} \rangle^M &= \frac{1}{2} \langle H_{SB} \rangle_{Eq} \\ &+ \frac{1}{2} \sum_k \eta_k Tr[(b_k + b_k^\dagger) \sigma_z \sigma_x \sigma_z \rho_{Eq}] \\ &= \frac{1}{2} \langle H_{SB} \rangle_{Eq} - \frac{1}{2} \langle H_{SB} \rangle_{Eq} = 0, \end{aligned} \quad (24)$$

where we have used the identity $\sigma_z \sigma_x \sigma_z = -\sigma_x$.

This expresses the vanishing of $Tr \{ \rho_{tot}(\tau) H_{SB} \}^M$ due to the diagonality of $\rho_{tot}^M(\tau)$ with respect to S . Since $H_D = 0$, the detector mean energy is not affected by the measurement.

B. Post-measurement heating

As shown in (III A) above, a nearly-impulsive (projective) quantum measurement ($\tau \rightarrow 0$) of S , in the $|g\rangle, |e\rangle$ basis, using the energy supplied by $H_{SD}(0 < t < \tau)$ eliminates the mean system-bath interaction energy. Now the pre-measurement equilibrium mean value, $\langle H_{SB} \rangle_{Eq}$, is *negative*, as is shown above (Eq. (13a)) by second-order perturbation theory, provided the temperature is positive, i.e., the $|g\rangle$ state is populated more than the $|e\rangle$

state at thermal equilibrium. Hence

$$\begin{aligned} \langle H_{SB}(0) \rangle_{Eq} < 0 &\mapsto \langle H_{SB}(\tau) \rangle^M = 0, \\ \langle H_{SD}(t) \rangle &= -\langle H_{SB}(t) \rangle^M. \end{aligned} \quad (25)$$

After the measurement (as $H_{SD}(t \geq \tau) = 0$), time-energy uncertainty at $\Delta t \lesssim 1/\omega_a$ results in the breakdown of the RWA, i.e., $\langle H_S + H_B \rangle$ is not conserved as Δt grows. The resulting $\langle H_S \rangle + \langle H_B \rangle$ changes stem from the non-commutativity of H_{SB} and H_{SD} . Only $\langle H_{tot} \rangle$ is conserved, by unitarity, until the next measurement. Hence, the *post-measurement decrease* of $\langle H_{SB} \rangle$ with Δt , signifying the restoration of equilibrium:

$$\langle H_{SB}(\tau) \rangle^M = 0 \rightarrow \langle H_{SB}(\tau + \Delta t) \rangle < 0, \quad (26)$$

is at the expense of the *increase*

$$\langle H_S + H_B \rangle = \langle H_{tot} \rangle - \langle H_{SB} \rangle > 0, \quad (27)$$

i.e., *heating* of the system and the bath (Fig. 2, 3), combined.

FIG. 2: System evolution as a function of time. Excited-level population as a function of time for initially zero-temperature product state, followed by relaxation to quasi-equilibrium and then subjected to a series of measurements (vertical dashed lines). Measurements of finite duration ($\tau_k = 0.11/\omega_a$) (blue line) results in somewhat larger heat-up than impulsive measurements (red line), but the dominant effect is the same for both. Observe the agreement between 2^{nd} order master equation (green), two-quanta exchange with a discrete bath, and exact numerical solution for a discrete bath of 40 modes (black dashed). Parameters: memory time of the bath $t_c = 10/\omega_a$, peak of the bath spectrum $\omega_0 = \omega_a$, maximal coupling strength to the bath $|\eta_{max}|^2 = 0.07\omega_a$, where $\hbar\omega_a$ is the energy separation of the TLS.

C. Short-time post-measurement qubit evolution

Let us denote the even part of the bath state by $|B^{even}\rangle|e\rangle$ and that of the odd part as $|B^{odd}\rangle$, then:

FIG. 3: Excitations as a function of t of the 40 modes in the two-quanta model. λ is the mode number. Parameters as in Fig. 2

$$|B_{n,g}^{even}(t)\rangle \otimes |g\rangle + |B_{n,g}^{odd}(t)\rangle \otimes |e\rangle \equiv |\Psi_{n,g}(t)\rangle. \quad (28)$$

Here B^{even} (respectively, B^{odd}) is a combination of bath $\hat{N}$ -eigenstates with eigenvalues differing from $\hat{N}$ by even (respectively, odd) numbers.

The post-measurement evolution of the system alone, described by $\rho_S = Tr_B \rho_{tot}$, is not at all obvious. Its Taylor expansion holds at short evolution times, $\Delta t \ll 1/\omega_a$,

$$\rho_S(\tau + \Delta t) \simeq \rho_S(\tau) + \Delta t \dot{\rho}_S(\tau) + \frac{\Delta t^2}{2} \ddot{\rho}_S(\tau) + \dots \quad (29)$$

The 0th order term is *unchanged* by the measurement, $\rho_S(\tau) = \rho_S(t \leq 0)$.

Due to the post-measurement vanishing of the off-diagonal elements of ρ_{tot} (Eq. (21), for $\rho_{tot}(t) = |\Psi_{n,g}(t)\rangle \langle \Psi_{n,g}(t)|$ (Eq. (28)), we have

$$\begin{aligned} (\rho_S)_{eg}(t) &= \langle e | \rho_S(t) | g \rangle = Tr_B \langle e | \rho_{tot}(t) | g \rangle \\ &= \langle B_{n,e}^{even}(t) | B_{n,e}^{odd}(t) \rangle = 0 \end{aligned} \quad (30)$$

Hence, ρ_S is diagonal at any time t .

Its derivative immediately after the measurement, $\dot{\rho}_S(\tau)$, has the form:

$$\begin{aligned} \dot{\rho}_S(\tau) &= -ie^{-i\omega_a\tau} |e\rangle \langle g | Tr_B \{ \mathcal{B}(\rho_{gg}^B - \rho_{ee}^B) \} + H.C. \\ &= 0. \end{aligned} \quad (31)$$

The same argument goes through upon permuting $e \leftrightarrow g$ everywhere for $\rho_{tot} = |\Psi_{n,e}(t)\rangle \langle \Psi_{n,e}(t)|$.

Hence, the first derivative *vanishes* at $t = \tau$ ($\Delta t = 0$) due to the definite parity of the bath density-operator correlated to $|g\rangle$ or $|e\rangle$. This post-measurement vanishing of the first derivative, $\dot{\rho}_S(\tau) = 0$, is the condition for the quantum Zeno effect (QZE)[11, 13, 14, 15]. The time evolution of ρ_S is then governed by its second time derivative $\ddot{\rho}_S(\tau)$.

For the *factorisable* thermal state,

$$\rho_{tot} = Z^{-1} e^{-\beta H_0} = Z_B^{-1} e^{-\beta H_B} Z_S^{-1} e^{-\beta H_S}, \quad (32)$$

we have:

$$\begin{aligned} \rho_{ee}^B &\equiv \langle e | \rho_{tot} | e \rangle = \langle e | Z_S^{-1} e^{-\beta H_S} | e \rangle Z_B^{-1} e^{-\beta H_B} \\ &= (\rho_S)_{ee} \rho_B \text{ (and } e \leftrightarrow g). \end{aligned} \quad (33)$$

For this ρ_{tot} , the second derivative of ρ_S immediately after the measurement is (cf. Eq. (21))

$$\ddot{\rho}_S(\tau) = 2\sigma_z Tr_B \{ \hat{\mathcal{B}}^2 (\rho_{gg}^B - \rho_{ee}^B) \}. \quad (34)$$

The scalar factor is positive:

$$\begin{aligned} Tr_B \{ \hat{\mathcal{B}}^2 (\rho_{gg}^B - \rho_{ee}^B) \} \\ = Tr_B \{ \hat{\mathcal{B}}^2 \rho_B \} \left((\rho_S)_{gg} - (\rho_S)_{ee} \right) > 0, \end{aligned} \quad (35)$$

where we have used $Tr_B \{ \rho_{gg}^B \} = (\rho_S)_{gg}$ which follows from the definition (Eq.(21)): $\rho_{ee}^B = \langle e(g) | \rho_{tot} | e(g) \rangle$. The first factor in (35) is positive by virtue of the positivity of the operator $\hat{\mathcal{B}}^2$ ($\hat{\mathcal{B}}$ being Hermitian), and the second is positive iff there is no population inversion for the TLS.

Hence, the second derivative in (29) is *positive* shortly after the measurement, if there is no initial population inversion of the system, i.e., for non-negative temperature.

D. Post-measurement state

The combined (system- and bath-) equilibrium state satisfies:

$$\rho_{tot}^M = Z^{-1} e^{-\beta H_{tot}} = \rho_{tot} = Z^{-1} e^{-\beta (H_0 + O(H_{SB}^2))}. \quad (36)$$

Thus, for sufficiently weak coupling, Eq. (33) dominates.

How is this reconciled with the non-unitary nature of the projection, whereby the mixedness of the total state must increase? Indeed,

$$Tr[(\rho^M)^2] = \frac{1}{2} Tr[(\rho_{Eq})^2] + \frac{1}{2} Tr[(\sigma_z \rho_{Eq} \sigma_z \rho_{Eq})] \quad (37)$$

Yet, in the weak-coupling limit, the increase in mixedness due to measurement is $\cong O(\epsilon^4)$ and hence can be neglected.

IV. POST-MEASUREMENT FREE EVOLUTION OF THE QUBIT

The evolution of ρ_S at longer times (in the regime of weak system-bath coupling) may be approximately described (as verified by our *exact* numerical simulations[16]) by the second-order non-Markovian master equation (ME)[17] (Fig. 2). Higher-order corrections

to the ME will be discussed elsewhere. The 2nd order ME for ρ_S , on account of its diagonality, can be cast into the following population rate equations[11], dropping the subscript S in what follows and setting the measurement time to be $t = 0$:

$$\dot{\rho}_{ee}(t) = -\dot{\rho}_{gg}(t) = R_g(t)\rho_{gg} - R_e(t)\rho_{ee}, \quad (38)$$

$$R_{e(g)}(t) = 2\pi t \int_{-\infty}^{\infty} d\omega G_T(\omega) \text{sinc}[(\omega \mp \omega_a)t]. \quad (39)$$

Here $\text{sinc}(x) = \frac{\sin(x)}{x}$. We shall assume that $G_0(\omega)$, the zero-temperature coupling spectrum, has peak coupling strength at ω_0 and spectral width $\sim 1/t_c$.

FIG. 4: Relaxation rates, R_g (dashed) and R_e (solid) as a function of time. Parameters as in Fig. 2.

FIG. 5: $R_g(t)$ and $R_e(t)$ (Eq. (39)) depicted as spectral overlaps of coupling spectrum (blue solid) and $\text{sinc}((\omega \pm \omega_a)t)$ (black dashed).

The entire dynamics is determined by $R_{e(g)}(t)$ (Figs. 4, 5), the relaxation rates of the excited (ground) states:

(i) At short times $t \ll 1/\omega_a \ll t_c$ the sinc function in (39) is much broader than G_T . The relaxation rates R_e and R_g are then equal at any temperature, indicating the

complete breakdown of the RWA discussed above: $|g\rangle \rightarrow |e\rangle$ and $|e\rangle \rightarrow |g\rangle$ transitions do not require quantum absorption or emission by the bath, respectively. The rates $R_{e(g)}$ then become *linear* in time, manifesting the QZE[11, 14, 15]:

$$R_{e(g)}(t \ll t_c) \approx 2\dot{R}_0 t, \quad (40)$$

$$\dot{R}_0 \equiv \int_{-\infty}^{\infty} d\omega G_T(\omega) = \langle \mathcal{B}^2 \rangle. \quad (41)$$

This short-time regime entails the *universal Zeno heating rate*:

$$\frac{d}{dt}(\rho_{ee} - \rho_{gg}) \approx 4\dot{R}_0 t(\rho_{gg} - \rho_{ee}). \quad (42)$$

(ii) At intermediate non-Markovian times, $t \sim 1/\omega_a$, when the sinc function and G_T in $\dot{R}$ -def have comparable widths, the relaxation rates $R_{e(g)}(t)$ exhibit several unusual phenomena that stem from time-energy uncertainty. The change in the overlap of the sinc and G_T functions with time results in damped aperiodic oscillations of $R_e(t)$ and $R_g(t)$, near the frequencies $\omega_0 - \omega_a$ and $\omega_0 + \omega_a$, respectively. This oscillatory time dependence that conforms neither to QZE nor to the converse AZE of relaxation speedup[14, 15, 18], will henceforth be dubbed the *oscillatory Zeno effect* (OZE). Due to the negativity of the sinc function between its consecutive maxima, we can have a *negative relaxation rate*, which is completely forbidden by the RWA. Since $\text{sinc}[(\omega + \omega_a)t]$ is much further shifted from the peak of $G_T(\omega)$ than $\text{sinc}[(\omega - \omega_a)t]$, $R_g(t)$ is more likely to be negative than $R_e(t)$ (Figs. 4, 5). Hence, $\rho_{gg}(t)$ may grow at the expense of $\rho_{ee}(t)$ more than allowed by the thermal-equilibrium detailed balance. This may cause *transient cooling*, as detailed below.

(iii) At long times $t \gg t_c$, the relaxation rates attain their Golden-Rule (Markov) values[11]

$$R_{e(g)}(t \gg t_c) \simeq 2\pi G_T(\pm\omega_a). \quad (43)$$

The populations then approach those of an equilibrium Gibbs state whose temperature is equal to that of the thermal bath (Fig. 2).

If we repeat this procedure often enough, the TLS will either increasingly heat up or cool down, upon choosing the time intervals Δt_k to coincide with either peaks or troughs of the ρ_{ee} oscillations, respectively. Since consecutive measurements affect the bath and the system differently, they may acquire different temperatures, which then become the initial conditions for subsequent QZE heating or OZE cooling, Fig. 6. The results are shown for both different and common (Fig. 7) temperatures of the system and the bath. Remarkably, the system may heat up solely due to the QZE, although the *bath is colder*, or cool down solely due to the OZE or AZE, although the *bath is hotter*. The bath may undergo changes in temperature and entropy too (Fig. 3).

FIG. 6: Example of a system experiencing first Zeno heating, then *oscillatory-Zeno cooling*, obtained from the second-order master equation (black-solid) and from the exact numerical solution for a discrete bath of 40 modes (blue dashed).

FIG. 7: Maximal Zeno heating (blue solid) and subsequent maximal cooling (black dashed) as a function of common initial temperature of system and bath $\alpha_S = \alpha_B = \hbar\omega_a\beta$. Note the *critical temperature* for oscillatory-Zeno cooling. Parameters: memory time of the bath $t_c = 10/\omega_a$, peak of the bath spectrum $\omega_0 = \omega_a/0.7$, maximal coupling strength to the bath $|\eta_{max}|^2 = 4.36\omega_a$. These effects can be *strongly magnified* by choosing other suitable parameters.

V. DERIVATION OF COOLING CONDITIONS

By integrating Eq. (39) over time to acquire $J_{g(e)}(t)$, one arrives at the following result:

$$J_g(t) = \int_0^\infty d\omega G_0(\omega) n_T(\omega) \text{sinc}^2((\omega - \omega_a)t) + \int_0^\infty d\omega G_0(\omega) (n_T(\omega) + 1) \text{sinc}^2((\omega + \omega_a)t) \quad (44)$$

$$J_e(t) = \int_0^\infty d\omega G_0(\omega) n_T(\omega) \text{sinc}^2((\omega + \omega_a)t) + \int_0^\infty d\omega G_0(\omega) (n_T(\omega) + 1) \text{sinc}^2((\omega - \omega_a)t) \quad (45)$$

To obtain cooling below the equilibrium temperature, one requires that:

$$\frac{J_e(t)}{J_g(t)} > \frac{J_e^{Eq}}{J_g^{Eq}} = \frac{R_e^{Eq}}{R_g^{Eq}} = \frac{n(\omega_a)}{n(\omega_a) + 1} \quad (46)$$

Rearranging the terms in the above equation, gives the cooling condition,

$$\int_0^\infty G_0(\omega) \frac{\sin^2 \left[\frac{t}{2}(\omega - \omega_a) \right]}{(\omega - \omega_a)^2} (n_T(\omega_a) - n_T(\omega)) > \int_0^\infty G_0(\omega) \frac{\sin^2 \left[\frac{t}{2}(\omega + \omega_a) \right]}{(\omega + \omega_a)^2} (n_T(\omega_a) + n_T(\omega) + 1) \quad (47)$$

A general quest for finding the spectral density function $G_0(\omega)$, which satisfies the above condition in some time interval, at any given temperature T , is quite difficult. In the high temperature limit i.e., $n_T(\omega) \gg 1$ one can find a necessary condition on the peak position of $G_0(\omega)$, which can satisfy the above inequality. Substituting the high-temperature limit for $n_T(\omega) \simeq 1/\beta\omega$, one can show that in order to allow cooling $G_0(\omega)$ needs to be concentrated in the frequency interval defined by

$$\omega_a < \omega < \Omega, \quad (48)$$

where

$$\beta\Omega = 1 + \frac{\beta\omega_a + \sqrt{4 + 12\beta\omega_a + \beta^2\omega_a^2}}{2}. \quad (49)$$

Though $\beta\Omega > 1$, it is only the maximum possible bound on the detuning of the bath spectrum for the qubit frequency, indicating that one should not detune the bath spectrum too far from ω_a to see the cooling effect. We have numerically verified these conditions for various bath coupling spectrums. In the same spirit one can find regions in frequency space, where for specific times there will be no cooling, independent of the shape of $G_0(\omega)$.

VI. ENTROPY DYNAMICS

One may always define the entropy of ρ_S relative to its equilibrium state ρ_0 (“entropy distance”) and the negative of its rate of change, as[3, 5]:

$$\begin{aligned} S(\rho_S(t)||\rho_0) \\ \equiv \text{Tr}\{\rho_S(t) \ln \rho_S(t)\} - \text{Tr}\{\rho_S(t) \ln \rho_0\} \end{aligned} \quad (50)$$

$$\sigma(t) \equiv -\frac{d}{dt} S(\rho_S(t)||\rho_0). \quad (51)$$

In the Markovian realm $\sigma(t) \geq 0$ [2, 3, 5] is a statement of the second law of thermodynamics. Since ρ_S is diagonal, it follows that $\sigma(t)$ is positive iff $\frac{d}{dt} |\rho_{ee}(t) - (\rho_0)_{ee}| \leq 0$, consistently with the interpretation of the relative entropy $S(\rho_S||\rho_0)$ in (51) as the entropic “distance” from equilibrium. Conversely, whenever the oscillatory $\rho_{ee}(t)$ drifts away from its initial or final equilibria, σ takes negative values (Fig. 8).

FIG. 8: $\sigma(t)$ (negative of relative entropy rate of change). Parameters as in Fig. 2.

VII. DISCUSSION: REALIZATION AND PRACTICAL CONSEQUENCES

Consider atoms or molecules in a microwave cavity (Fig. 9(a)) with controllable finite-temperature coupling spectrum $G_T(\omega)$ centered at ω_0 . Measurements can be effected on such a TLS ensemble with resonance frequency ω_a in the microwave domain, at time intervals $\Delta t_k \sim 1/(\omega_0 \pm \omega_a)$, by an optical QND probe[19] at frequency $\omega_p \gg \omega_a, \omega_0$. The probe pulses undergo different Kerr-nonlinear phase shifts $\Delta\phi_e$ or $\Delta\phi_g$ depending on the different symmetries (e.g., angular momenta) of $|e\rangle$ and $|g\rangle$. The relative abundance of $\Delta\phi_e$ and $\Delta\phi_g$ would then reflect the ratio $\rho_{ee}(t_k)/\rho_{gg}(t_k)$. Such QND probing may be performed with time-duration *much shorter than* ω_a^{-1} , i.e. $\omega_a \tau_k \ll 1$, *without resolving the energies* of $|e\rangle$ and $|g\rangle$.

An experimental scenario involves collective N-atom coupling to near-resonant RF resonator (Fig. 9(a)). Let us choose ground sublevels $|m = -1\rangle \equiv |g\rangle$, $|m = +1\rangle \equiv |e\rangle$, with Zeeman splitting $\omega_{eg} \cong MHz$. The collective Rabi frequency of $N \geq 10^8$ atoms at a cavity antinode is $N^{1/2}\Omega_{eg}/2\pi \cong 100KHz$. An optical beam will rotate in polarization (Fig. 9(b)), thus performing QND measurement (readout) that resolves $|g\rangle$ and $|e\rangle$ (by their symmetry, not by energy) if its Rabi frequency:

$$\Omega_{read} \cong N^{1/2}(\Omega_0)_{read}^2/\Delta \geq \omega_{eg}. \quad (52)$$

Such a Rabi frequency corresponds to RWA violation, as

FIG. 9: Possible experimental setup

discussed in the text above.

Non-selective measurements increase the Von-Neumann entropy of the detector ancillae. Since our ancillae are laser pulses, they are only used once and we may progressively change the TLS ensemble thermodynamics by consecutive pulses, disregarding their entropic or energetic price.

VIII. CONCLUSIONS

To conclude, we have shown that frequent QND measurements may induce either anomalous heating or anomalous cooling of TLS coupled to baths on non-Markovian time scales. These findings defy the standard notions of quantum thermodynamics regarding system equilibration in the presence of a thermal bath.

The practical advantage of the predicted anomalies is the possibility of *very rapid control* of cooling and entropy, which may be attained after several measurements at $t \geq \omega_a^{-1}$ and is only limited by the measurement rate. By contrast, conventional cooling requires much longer times, $t \gg t_c$, to reach thermal equilibrium.
